Size: A3	Date: 2023-11-28	**Rev: 1.0**
KiCad E.D.A. kicad 7.0.9		Id: 1/20

Provides a clock pulse and inverted clock pulse.
Speed can be set with the potentiometer.
Manual pulse can be chosen with the switch and pulsed with the button.
If HALT is HIGH no pulse is outputted.

The outputs of the 74HCT173 are always on.
(OE1 and OE2 are tied to ground)
This is done for demonstration purposes
so the content can be seen via leds.

To put the register data on the bus
the 74HCT245 is used.
This chip not really needed in
normal circumstances.

A word on the RESET line.
On my breadboards this is giving me a lot of problems.
When there are 4 or more lines high on the RAM value
and I toggle between RAM_OUTPUT and not RAM_OUTPUT
the RAM address gets RESET for some reason.
After trying everything I could think of (pull ups, pull downs,
disconnecting the bus, replacing chips, replacing wires, ...)
I got nowhere. So I decided to disconnect the RESET line from the
flip flops and just tie them to GND.
RESET for the RAM address is not really needed given the pogram
loads the first address from the program counter which is 0.
I might hook it up again and see once all the control
signals are connected.

This is not reflected in the schematic because I do not know if
it is related to the breadboards or not.

When in programming mode the
value from the dip-switches is selected.
Otherwise the values from the flip flops are selected.

This logic generates the signal to enable
either the left bank or the right bank of the RAM.
In its default state the read bank is enabled.
When in programming mode, the write bank gets enabled by a push button.
In run mode the write bank gets enabled when RAM_INPUT and CLOCK are high.
In programming mode the STACK_ADDRESS is forced LOW to not inadvertedly write
to the stack.

For addressing the RAM there are 8 bits. (+ the 9th for the stack)
I want to separate the program memory from the program data.
For this I decided that the first 128 bytes are for the program memory.
These bytes cannot be written to in run mode.
So whenever RAM_INPUT is high and STACK_ADDRESS is high
we force the 8th bit to high.
In all other cases we are either reading, programming or writing to the stack
and we pass the original value of the 8th bit through.
